# Price Discovery Share-An Order Invariant Measure of Price Discovery with Application to Exchange-Traded Funds*

Syed Galib Sultan[†]

Eric Zivot[‡]

August 11, 2020

## Abstract

Price Discovery is the process by which new information is impounded into asset prices through trading activity. A market is considered to contribute more to price discovery if it is the first to capture new information regarding the fundamental value of an asset. Hasbrouck's (1995) information share (IS) is the most widely used empirical measure for a market's price discovery contribution even though there is a well-documented concern with identification: its dependence on the ordering of price variables and its non-uniqueness. We propose a closely related measure which we call 'price discovery share' (PDS) that is unique and order invariant. PDS is motivated by a widely used method in portfolio risk management to additively decompose portfolio volatility into asset specific contributions. Using simulated data based on different structural asset pricing models, we show that PDS measures structural price discovery contributions more accurately than IS. We apply PDS to investigate the "duplication of Exchange-Traded Funds (ETFs)" phenomenon, a recent institutional trend in financial markets. We show that although there are multiple ETFs tracking the S&P 500 index, one specific S&P 500 ETF, SPY, always contributes more to price discovery than the rest.

**Keywords**: price discovery, information share, Exchange-traded Funds (ETFs)

# 1 Introduction

New market trends have made price discovery, the process by which new information is impounded into asset prices through trading activity, an important research agenda in the financial economics literature. Recent features of financial markets include the trading of identical assets in multiple venues (also known as market fragmentation) and the trading of closely related assets (e.g., derivatives, futures and spot, ETFs tracking the same market index, etc.) in the same or different venues. Hasbrouck's (1995) information share (IS) is the most widely used empirical measure to identify and quantify the process of price discovery.[1] IS is typically interpreted as identifying who moves first in the process of price adjustment when a new trade related information or permanent shock is received.

IS has been used by numerous studies in different financial market related contexts.[2] However, it is well-documented that IS has a potentially serious identification problem when idiosyncratic innovations to different market prices in Hasbrouck's (1995) model are contemporaneously correlated. When the correlation is significantly high, the IS measure, which is typically reported as a range, can become very wide and does not clearly identify the price/information leader or the follower and their individual contributions to price discovery. This limitation has been referred to in previous literature as the 'order-dependence problem of IS', because the upper and the lower bound of the range that IS reports depends on the order that the prices enter into the vector of prices. Numerous studies have proposed different solutions and measures to address this shortcoming of IS. However, no consensus has emerged so far because all of the proposed alternatives (see Hasbrouck, 1995; Baillie et al, 2002; Lien and Shrestha, 2009 and Grammig and Peter, 2014) have been found to be either only effectively in particular context or to have their own identification issues[3].

---

[1] The 2003 special issue on price discovery in the Journal of Financial Markets gives an excellent review of price discovery measures.

[2] IS has been applied to cross-listed stock to determine the information or price leadership among different stock exchanges (Hasbrouck, 1995; Huang, 2002; Harris et al.,2002) . IS has also been used to determine the information or price leadership between quotes and trade prices of stock (Hasbrouck, 2002), between stock options and underlying stocks (Chakravarty et al., 2004), between futures and their spots (Mizarch and Neely, 2008; Lien and Shrestha 2009), among Credit Default Swap (CDS), bonds and stocks (Grammig and Peter 2014) etc. Also, a brief summary of different studies which use IS can be found in pp- 78 of Putnins (2013).

[3] Hasbrouck (1995) suggests sampling the trade and quote prices at a high enough frequency such that contemporaneous correlation among the innovations becomes negligible. However, numerous studies includ-

In this paper we address the identification problem of IS and propose a closely related measure for price discovery that is unique and order-invariant. Our measure of price discovery is motivated by a widely used method in portfolio risk management literature to additively decompose portfolio volatility into asset specific contributions. [4] A notable feature of Hasbrouck's (1995) model is that the volatility of the efficient price innovation (VEPI henceforth) is linearly homogeneous in the common factor weights of each market's innovation just as portfolio volatility is linearly homogeneous to its portfolio weights. We use this property and apply Euler's theorem to additively decompose the VEPI into components attributed to each market. Each of these components is defined as the contribution of each market to VEPI. Moreover, a key component of this decomposition is what we call price discovery beta of a market. Price discovery beta of a market is the regression coefficient of a market's innovation on the efficient price innovation. We convert the calculated market contributions to market shares by dividing these contributions by the VEPI. Our new measure of price discovery for each market is this contribution share which we call price discovery share (PDS).

PDS is applicable to the general $n$-assets or $n$-markets model. As a special case, we provide the analytical comparison between IS, IS-mean and PDS in a simple bi-variate case. We also compare IS and PDS using simulated market data. We generate simulated asset price data following four different structural asset pricing models and compare the sample properties of IS and PDS. In every case, PDS is found to estimate the true structural price discovery contribution more accurately than IS.[5]

---

ing ours find that even with the use of bid-ask quotes sampled at a 1-second interval there is still enough residual correlation to produce a wide range for IS. Baillie et al. (2002) argue in support of using the mean or mid-point of the upper and lower bound of the range as a unique measure of IS. This approach, while intuitively appealing, is ad hoc. Lien and Shrestha (2009) correctly point out that the average of the two bounds of IS cannot be derived as a result of any particular factor structure. In addition, the calculated means or mid-points of the estimated individual price discovery contributions often do not add up to 100% in applications with more than two prices. Lien and Shrestha (2009) alternatively propose a modified information share (MIS) measure that is derived from the squared root of the eigenvalues of the innovation correlation matrix. A limitation of this approach is that it considers only the positive value of squared root of the eigenvalues in order to reach a unique result. If the negative values of the squared root of the eigenvalues are considered, then it would produce a different value for the MIS. Grammig and Peter (2014) propose another unique measure for IS which is derived by exploiting two properties of price changes -fat tails and tail-dependence.

[4]See Bruder and Roncalli (2012) for a nice description of "risk budgeting" or the additive decomposition of portfolio volatility and use of Euler theorem to determine individual risk contribution of assets in a portfolio.

[5]Due to the popularity of Baillie et al (2002) measure in different literature, we have decided to report

Another contribution of this paper to the price discovery literature is our application of PDS in an empirical investigation of price discovery in the market of exchange-traded funds (ETFs) that track the S&P 500 index. ETFs are defined as securities that track the performance of market index, commodity and bonds like an index fund. ETFs can be traded like close-end mutual funds, that is, they can be traded throughout the day like a stock. ETFs are usually highly liquid assets with high tax-efficiency and very low expense ratio compared to mutual funds. All these favorable features have made ETFs extremely popular for investment and risk management purposes.

After the "Flash Crash" of May 6, 2010 ETF trading has also caught the attention of regulators and academicians alike. Sharp price falls across a disproportionate number of ETFs during the "Flash Crash" have been deemed to be responsible for the abrupt market crash.[6] An investigative report by Borkovec, Domowitz, Serbin and Yegerman (2010) finds that price discovery failed dramatically for these ETF securities during the "Flash Crash". In this backdrop, understanding the price discovery dynamics in the ETFs has become an important research agenda.

A recent trend in financial markets, which is relatively unexplored in the price discovery literature, is the proliferation of multiple ETFs tracking the same index. In this paper, we denote this as "duplication of ETFs". The natural research question that rises from this trend is "what is the rationale behind the 'duplication of ETFs' and what is its effect on price discovery?". In this study, we mainly focus on the effect of ETF duplication on price discovery. We select a particular index ETF, the S&P 500 ETF, and study price discovery between two nearly identical and competing S&P 500 ETFs. The two S&P 500 ETFs we consider are SPY (issued by SPDR State Street Global Advisors) and IVV (issued by iShares of Blackrock).[7] We investigate price discovery between these two competing ETFs during a regular trading week in 2012 and also, during two highly volatile trading days in recent

---

this measure along with upper and lower bound of IS in our analysis. We call this measure "IS-mean".

[6] According to the joint SEC/CFTC flash Crash Report, "ETFs accounted for 70% of all US-listed securities that declined by 60% or more during the May 6, 2010 Flash Crash". See Borkovec, Domowitz, Serbin and Yegerman (2010)

[7] SPY is the largest, oldest and most popular ETF of its kind which was issued by SPDR State Street Global Advisors for public trading in 1993. IVV is the second most popular ETF that tracks S&P 500 index. It was first issued in 2000 by iShares of Blackrock. More information regarding these ETFs can be found in section 4.1.

years–the 'Flash Crash' on May 6th, 2010 and the stock market fall on August 8th, 2011 (two days after the US lost its AAA credit rating). SPY is found to be the price leader in all instances and particularly, during the 'Flash Crash', and it is found to be the absolute price leader with more than 95% share of price discovery.

We also provide a comparative assessment of IS and PDS in two different empirical settings. First, we use our "duplication of ETF" application to show that even with one-second tick-by-tick quotes, IS can report very misleading results with wide ranges of price discovery shares. By contrast, PDS always provides a clean decomposition and a unique value of price discovery contribution. Second, we use quotes of the single day (Dec 3rd, 2012) of the cross-listed ETF, "SPY", to calculate price discovery share across two stock exchanges (NASDAQ and BATS). We compare the estimates of IS and PDS using quotes sampled at different frequencies. IS reports misleading results whereas, PDS results are consistent and also robust to the use of quotes data with higher time intervals.

The remainder of the paper is organized as follows. In Section II, we describe the reduced-form cointegration framework used by Hasbrouck (1995) for modeling price discovery in arbitrage linked market and also define our new measure of price discovery, PDS. In Section III, we compare PDS to IS using simulated market data generated from different structural models of asset prices. Section IV presents our empirical application in S&P 500 ETFs and evaluates the effect of "duplication of ETFs" on price discovery. In Section V, we compare the performance of IS and PDS in two different empirical settings. Finally, we conclude with a brief summary of the paper's findings and provide some guidelines for future research.

## 2 Model description

We use the arbitrage-linked cointegration model approach of Hasbrouck (1995). Let $P_t = (p_{1,t}, \cdots, p_{n,t})'$ denote an $n \times 1$ vector of $I(1)$ log prices. In the price discovery literature, $P_t$ either represents the vector of prices of a single asset that is traded in $n$ market locations and linked by arbitrage, or the vector of prices of $n$ similar or closely related and arbitrage linked assets that are being traded in the same market location.

It is assumed that there is a common stochastic component or fundamental value that

drives all arbitrage-linked prices. As a result, there are $n-1$ cointegrating vectors $\theta_i$ such that, $\theta_i'P_t \sim I(0)$. Furthermore, since the difference between two prices is *I(0)*, it is convenient to use the following $(n-1) \times n$ matrix of rank *n - 1* as a basis for the cointegrating space:

$$\Theta' = \begin{bmatrix} \theta_1' \\ \vdots \\ \vdots \\ \theta_{n-1}' \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 & \cdots & 0 \\ 1 & 0 & -1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 1 & 0 & 0 & \cdots & -1 \end{bmatrix} = \left( 1_{n-1} \quad \vdots \quad -I_{n-1} \right) \tag{1}$$

where $1_{n-1}$ is an $(n-1) \times 1$ vector of ones and $I_{n-1}$ is the identity matrix of dimension *n-1*.

Since $\Delta P_t$ is I(0), it has a Wold representation:

$$\Delta P_t = \Psi(L)e_t = e_t + \Psi_1 e_{t-1} + \Psi_2 e_{t-2} + ....,  \tag{2}$$

where $\Psi(L) = \sum_{k=0}^{\infty} \Psi_k L^k, \Psi_0 = I_n$, $e_t = (e_{1t}, \ldots, e_{nt})'$ and $e_t \sim iid(0, \Sigma)$ where $\Sigma$ is $n \times n$ matrix and has elements $\sigma_{ij}$. It is assumed that elements of $\Psi(L)$ are 1-summable and $\Psi(1) \neq 0$. Using the Beveridge-Nelson decomposition (Beveridge and Nelson, 1981), we can write:

$$P_t = P_0 + \Psi(1) \sum_{j=0}^{t} e_j + \Psi^*(L)e_t \tag{3}$$

where $P_0$ is $n \times 1$ vector of initial values, $\Psi(1) = \sum_{k=0}^{\infty} \Psi_k, \Psi^*(L) = \sum_{k=0}^{\infty} \Psi_k^* L^k$ and $\Psi_k^* = - \sum_{j=k+1}^{\infty} \Psi_j$. Moreover, $\Psi^*(L)e_t \sim I(0)$ and $\theta'\Psi(1) = 0$. The restriction $\theta'\Psi(1) = 0$ implies that the $n \times n$ matrix $\Psi(1)$ has rank one and can be expressed as

$$\Psi(1) = 1_n \psi' = \begin{bmatrix} \psi_1 & \cdots & \psi_n \\ \vdots & \ddots & \vdots \\ \psi_1 & \cdots & \psi_n \end{bmatrix} \tag{4}$$

where $\psi = (\psi_1, ..., \psi_n)'$. The matrix $\Psi(1)$ contains the cumulative impacts of the innovation $e_t$ on all future price movements, and thus measures the long-run impact of $e_t$ on prices. Since the rows of $\Psi(1)$ are identical, the long-run impact of $e_t$ on each price is identical.

Substituting (4) into (5) gives:

$$P_t = P_0 + 1_n \sum_{j=0}^{t} \eta_j^P + \tilde{\varepsilon}_t = P_0 + 1_n m_t + + \tilde{\varepsilon}_t \tag{5}$$

Here, $\tilde{\varepsilon}_t = (1 - L)\Psi^*(L)e_t$ is an I(0) pricing error vector, $\eta_t^P = \psi' e_t$ and $m_t = m_{t-1} + \eta_t^P = \sum_{j=0}^{t} \eta_j^P$ is the random walk component that is common to all prices. Here $\eta_t^P$ is the component of price changes that is permanently impounded into prices due to new information. Transient pricing errors such as bid-ask bounces and inventory adjustments are absorbed by the I(0) component $\tilde{\varepsilon}_t$.

## 2.1 Information Share

Hasbrouck (1995) defines the price discovery contribution of $i$-th market as its contribution to the permanent shock variance, $var(\eta_t^p) = \psi' \Sigma \psi$ divided by the $var(\eta_t^p)$. There are two cases to consider.

Case 1. $\Sigma$ is diagonal:

$$IS_i = \frac{(\psi_i \sigma_i)^2}{\psi' \Sigma \psi}, i = 1, ..., n \tag{6}$$

Case 2. $\Sigma$ is non-diagonal:

$$IS_i = \frac{((\psi' F)_i)^2}{\psi' \Sigma \psi}, i = 1, ..., n \tag{7}$$

where $(\psi' F)_i$ is the i-th element of $\psi' F$ and $F$ is a lower triangular matrix (Cholesky factor) such that $FF' = \Sigma$. The value of $F$ and hence, also the value of $IS_i$, depends on the ordering in which the individual prices enter into the vector of price, $P_t$. Therefore, when $\Sigma$ is non-diagonal, Hasbroucks's approach can only provide upper and lower bounds for $IS_i$ based on all possible orderings of prices in the vector. In particular, Baillie et al. (2002) show that largest information share for a given market occurs when its price is placed first in the price vector.

In practice, $IS_i(i = 1, ..., n)$ is computed from the estimated parameters of an empirical

VECM (K-1) for asset prices:

$$\Delta P_t = A(\Theta' P_{t-1} - \mu) + \sum_{j=1}^{K-1} \Gamma_j \Delta P_{t-j} + e_t \tag{8}$$

where $\Gamma_j$ is an $n \times 1$ matrix. The lag length, K, is typically chosen by some model selection criterion such as BIC or AIC. Because the cointegrating matrix $\Theta'$ is known, equation (8) can be estimated by least squares equation by equation. The long-run impact matrix, $\Psi(1)$ can be computed directly using Johansen's factorization and the estimation coefficients ($A$, $\Theta$ and $\Gamma_j$s) from the VECM:

$$\Psi(1) = \Theta_\perp (A'_\perp \Gamma(1) \Theta_\perp)^{-1} A'_\perp \tag{9}$$

where $\Theta_\perp$ and $A_\perp$ are vector satisfying $\Theta' \Theta_\perp = 0$ and $A' A_\perp = 0$, respectively. Also, $\Gamma(1) = I_n - \sum_{j=1}^{K-1} \Gamma_j$.

## 2.2   Price Discovery Share

Our new measure of price discovery is motivated by the additive decomposition of portfolio volatility that is widely used in portfolio risk management. Recall, the permanent shock is defined as a weighted average of individual market innovations $\eta_t^P = \psi' e_t$. The volatility of the permanent shock is $\sigma_\eta(\psi) = (\psi' \Sigma \psi)^{1/2}$. Now $\sigma_\eta(\psi)$ is linearly homogenous in $\psi$ since $\sigma_\eta(c \cdot \psi) = c \cdot \sigma_\eta(\psi)$ for any constant c. As a result we can apply Euler's theorem and derive the following additive decomposition of $\sigma_\eta(\psi)$ :

$$\sigma_\eta(\psi) = \psi' \frac{\partial \sigma_\eta(\psi)}{\partial \psi} = \sum_{i=1}^{n} \psi_i \frac{\partial \sigma_\eta(\psi)}{\partial \psi_i} = \psi_1 \frac{\partial \sigma_\eta(\psi)}{\partial \psi_1} + \cdots + \psi_n \frac{\partial \sigma_\eta(\psi)}{\partial \psi_n} \tag{10}$$

Equation (10) shows that the volatility of the permanent shock, $\sigma_\eta(\psi)$, can be expressed as the weighted sum of marginal contributions from each asset (or market $i$). The $i$-th term on the right-hand side of (10), $\psi_i \frac{\partial \sigma_\eta(\psi)}{\partial \psi_i}$, is asset i's (or market i's) contribution to the volatility of the permanent shock. In the spirit of Hasbrouck's information share, $\psi_i \frac{\partial \sigma_\eta(\psi)}{\partial \psi_i}$ is a natural measure of an asset's (or market's) contribution to price discovery. Our new order invariant

measure of an asset's (or market's) price discovery share, denoted $PDS_i$, is its contribution divided by $\sigma_\eta(\psi)$

$$PDS_i = \frac{\psi_i \frac{\partial \sigma_\eta(\psi)}{\partial \psi_i}}{\sigma_\eta(\psi)} \tag{11}$$

By construction $\sum_{i=1}^{n} PDS_i = 1$. By the chain rule:

$$\frac{\partial \sigma_\eta(\psi)}{\partial \psi} = \frac{\Sigma \psi}{\sigma_\eta(\psi)} = \sigma_\eta(\psi)\beta, \tag{12}$$

where $\beta = (\beta_1, ..., \beta_n)' = \frac{\Sigma \psi}{\sigma_\eta^2(\psi)}$. $\beta_i$ is defined as follows

$$\beta_i = \frac{cov(e_{it}, \eta_t^P)}{var(\eta_t^P)} = \frac{\psi_i \sigma_i^2 + \sum_{j=1}^{n-1} \psi_{j \neq i} \sigma_{ij \neq i}}{\psi' \Sigma \psi} \tag{13}$$

As a result, (11) may be re-expressed as

$$PDS_i = \psi_i \beta_i = \frac{\psi_i^2 \sigma_i^2 + \sum_{j=1}^{n-1} \psi_i \psi_{j \neq i} \sigma_{ij \neq i}}{\psi' \Sigma \psi} \tag{14}$$

We denote $\beta_i$ in equation (14) as the "*price discovery beta*" of asset $i$ (or market $i$). The *price discovery beta* is the slope coefficient from the regression of $\eta_t^P$ on $e_{it}$ and summarizes the (normalized) covariance contributions of an asset's (or market's) innovation to the variance of the efficient price innovation. Equatin (14) shows that $PDS_i$ is defined as asset $i$'s (or market $i$'s) contribution to the volatility of $\eta_t^P$ weighted by its *price discovery beta*.

## 2.3 Comparing PDS to IS

We consider the case of $n = 2$, so that $P_t = (p_{1,t}, p_{2,t})'$. This allows us to analytically compare PDS to IS easily. Under the assumption of uncorrelated innovations (diagonal $\Sigma$) and using equation (6) and equation (12), we find that $IS_i$ and $PDS_i$ are identical:

$$IS_{i,diag} = \frac{\psi_i^2 \sigma_i^2}{\psi' \Sigma \psi} = \frac{\psi_i^2 \sigma_i^2}{\psi_1^2 \sigma_1^2 + \psi_2^2 \sigma_2^2} = \psi_i \beta_i = PDS_{i,diag} \tag{15}$$

However, this is not the case when $\Sigma$ is non-diagonal. Let, $\Sigma = FF'$ where F is the $2 \times 2$ lower triangular matrix (Cholesky factor):

$$F = \begin{bmatrix} \sigma_1 & 0 \\ \rho\sigma_2 & \sigma_2(1-\rho)^{1/2} \end{bmatrix} \tag{16}$$

where $\rho^2 = \frac{\sigma_{12}^2}{\sigma_1^2 \sigma_2^2}$. Then, using equation (7), $IS_i$ ($i$ =1,2) is given by:

$$IS_{1,non-diag} = \frac{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2\rho^2 + 2\psi_1\psi_2\sigma_{12}}{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2 + 2\psi_1\psi_2\sigma_{12}} \tag{17}$$

$$IS_{2,non-diag} = \frac{\psi_2^2\sigma_2^2 - \psi_2^2\sigma_2^2\rho^2}{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2 + 2\psi_1\psi_2\sigma_{12}} \tag{18}$$

When the ordering of prices is reversed, $P_t = (p_{2,t}, p_{1,t})'$, the subscripts 1 and 2 get reversed in (17)−(18). Inspection of (17) and (18) shows that the highest (lowest) $IS_i$ value occurs when the price of asset $i$ (or market $i$) is ordered first (last) in the $P_t$. This produces the upper and lower bounds for $IS_i$ based on the ordering of prices. To get a unique value for $IS_i$, Bailie et al. (2002) proposed to use the mean of the upper and lower bounds of IS derived from (17) and (18):

$$IS_{1,mid} = \frac{\psi_1^2\sigma_1^2 + (\psi_2^2 - \psi_1^2)\sigma_2^2\rho^2 + \psi_1\psi_2\sigma_{12}}{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2 + 2\psi_1\psi_2\sigma_{12}} \tag{19}$$

$$IS_{2,mid} = \frac{\psi_2^2\sigma_2^2 + (\psi_1^2 - \psi_2^2)\sigma_2^2\rho^2 + \psi_1\psi_2\sigma_{12}}{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2 + 2\psi_1\psi_2\sigma_{12}} \tag{20}$$

From equation (11), $PDS_i$ ($i = 1,2$) values for non-diagonal $\Sigma$ are:

$$PDS_{1,non-diag} = \frac{\psi_1^2\sigma_1^2 + \psi_1\psi_2\sigma_{12}}{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2 + 2\psi_1\psi_2\sigma_{12}}, \tag{21}$$

$$PDS_{2,non-diag} = \frac{\psi_2^2\sigma_2^2 + \psi_1\psi_2\sigma_{12}}{\psi_1^2\sigma_1^2 + \psi_2^2\sigma_2^2 + 2\psi_1\psi_2\sigma_{12}}. \tag{22}$$

From equations (17) - (22), we make the following observations regarding IS, PDS and

IS-mid, when $\Sigma$ is non-diagonal. First, $PDS_i$ distributes the covariance contributions of each asset (or market) to the permanent shock variance or $\psi_1\psi_2\sigma_{12}$, evenly across assets (or markets). $PDS_1$ differs from $PDS_2$ only due to the difference between $\psi_1^2\sigma_1^2$ and $\psi_2^2\sigma_2^2$. Second, for $n > 2$, the calculation of the upper and lower bounds of $IS_i$ requires recalculation of equation (11) for all the possible orderings of prices. For example, when $n = 5$ there are 120 possible orderings of prices which need to be considered. Also, for each ordering, we will get different values of $IS_i$ from which we have to pick the highest and the lowest value in order to define the range of IS. The calculation of $PDS_i$ is invariant to the ordering of prices. Third, if $\psi_1 = \psi_2$ the mid-point $IS_i$ ($i = 1, 2$) values in equation (19) and (20) are equal to the $PDS_i$ ($i = 1, 2$) in equation (21) and (22). Fourth, it is possible for $PDS_i$ to be negative. This can happen if $\psi_i$ is negative and $\beta_i$ is positive in equation (14) and vice-versa. However, it is unusual for either $\psi_i$ or $\beta_i$ to be negative. It can be shown (cf. Zivot and Yan, 2010) that $\psi \propto \alpha_\perp$ where $\alpha_\perp$ is a $2 \times 1$ vector such that $\alpha_\perp'\alpha = 0$ and $\alpha = (\alpha_1, \alpha_2)'$ is the $2 \times 1$ vector of error correction coefficients from the VECM in (8) when $n = 2$. In typical applications, $\alpha_1$ and $\alpha_2$ have opposite signs so that $\psi_1$ and $\psi_2$ are both positive. However, it is possible to have a stable VECM with $\alpha_1$ and $\alpha_2$ having the same sign. In that case, $\psi_1$ and $\psi_2$ will have opposite signs and value of of $PDS_i$ will be negative. On the other hand, if $\psi_1$ and $\psi_2$ have the same sign, then $\beta_i = cov(e_{it}, \eta_t^P) = \psi_1\sigma_1^2 + \psi_2\sigma_{12}$ can still be negative if $\sigma_{12}$ is a sufficiently large negative number.[8]

# 3 Applications to simulated market data

In this section we use simulated market data to provide a comparison between IS and PDS. The simulated market data are generated from three different stylized structural models of asset prices described in Hasbrouck (2002).

---

[8]In the risk management context, an asset's contribution to portfolio volatility can be negative if it has a negative weight in the portfolio or if its beta with respect to the portfolio is negative (natural risk reducer). In the latter case the asset is negatively correlated with the portfolio.

## 3.1 Two-market "Roll" model

The first simulation example uses a model of high-frequency trade prices suggested by Roll (1984). In this model, the trade price has two components. One is the "efficient" or "fundamental" price which has the martingale property and follows a random walk. The other is a transient component which can arise from bid-ask bounce, inventory effects, discreteness, etc. This model assumes that there are two markets where a cross-listed identical stock is being traded at price $p_{1t}$ in Market 1 and at $p_{2t}$ in Market 2. The common efficient price of this stock is defined as,

$$m_t = m_{t-1} + u_t \tag{23}$$

where, $u_t \overset{iid}{\sim} N(0, \sigma^2)$. There is a common and identical fixed cost per trade in each market denoted by $c$. The bid-price at time •itt is $m_t - c$ and the ask-price at time $t$ is $m_t + c$. The trade-direction indicator denoted by $q_t$, which takes a value equal to 1 if the trader is buying and $-1$ if the trader is selling. Buys and sells are assumed to be equally likely and serially independent. The traders are also assumed to buy or sell independently of the innovation to efficient price (denoted by $u_t$). Therefore, trade direction and transaction price are defined as follows,

*Trade direction*: $q_{it} = \pm 1$, each with probability $\frac{1}{2}$ for i=1,2,

*Transaction price*: $p_{it} = m_t + cq_{it}$ for market =1,2.

From the set-up of the model, it is clear that the two markets are structurally identical and, therefore, the true share of each market to price discovery is 50%. Following Hasbrouck (2002) we set, $c = 1$ and $\sigma_u = 1$. We generate 100,000 observations of transaction prices, $p_{1t}$ and $p_{2t}$, for each market. We use the prices to estimate the VECM in (8) and use the estimated parameters to calculate IS, IS-mid and PDS. We repeat this process 1000 times and calculate the means and emprical 95% confidence intervals of these estimates .Table 1 reports the simulation results for Market 1. The results for Market 2 are identical.

**[Insert Table 1 here]**

From Table 1, we find that the mean values of PDS (50.1%) and IS-mean (50%) are very

close to the true price discovery share of 50%. However, the upper and lower bound of IS gives a large range [ 21.2%, 78.9% ].

## 3.2 Two markets with private information

In the second simulation, it is assumed that all the informed trading happen in Market 1. This implies that changes in an efficient price are driven only by trading activities in Market 1. The efficient price is defined as,

$$m_t = m_{t-1} + \lambda q_{1t} \tag{24}$$

where $\lambda$ is defined as a liquidity parameter and is assumed to be strictly positive. Trade directions $q_{it}$ are defined in similar way as in the first simulation example. The transaction price of Market 2 depends on the lagged value of $m_t$ which defines the Market 2 as the price follower.

$$\textit{Transaction price}: p_{1t} = m_t + cq_{1t} \text{ and } p_{2t} = m_{t-1} + cq_{2t}$$

The structural model suggests that all the price discovery happens in Market 1, so the true price discovery share of Market 1 is 100%. Following Hasbrouck (2002), we set $c = 1$ and $\lambda = 1$. We again generate 100,000 sample observations, calculate the IS, IS-mean and PDS and repeat this process 1000 times. Table 2 summarizes the moments and 95% confidence interval of each price discovery measure.

**[Insert Table 2 Here]**

From Table 2, we see that, all three price discovery measures accurately estimate the contribution of Market 1 to price discovery as 99.9%.

## 3.3 Two markets with private and public information

In the third simulation example, the efficient price, $m_t$, contains a non-trade public information component, $u_t$, and a private information component, $\lambda q_{1t}$, which is driven by Market 1's trade. Efficient price is defined as follows,

$$m_t = m_{t-1} + \lambda q_{1t} + u_t \tag{25}$$

where $u_t \overset{iid}{\sim} N(0, \sigma_u^2)$. Trade direction is defined as in the previous experiments. Trade costs for each market are now different from each other. The transaction price of Market 2 is again assumed to depend on lagged information regarding efficient price.

*Transaction price*: $p_{1t} = m_t + c_1 q_{1t}$ and $p_{2t} = m_{t-1} + c_2 q_{2t}$

Market 1 is the price leader with 100% price discovery share. $c_1$, the trading cost in Market 1 is higher than Market 2's, because the cost of market making is higher in Market 1 where all the informed traders are trading. Trades are done cheaply at stale prices in Market 2. For the simulation, we set $c_1 = 1$, $c_2 = 0$, $\lambda = 1$ and $\sigma_u = 1$. We conduct the simulation in the same way as before.

**[Insert Table 3 Here]**

Table 3 summarizes the results. The IS upper and lower bounds are 98.4% and 90% respectively. The mean of the PDS estimates is 96% which is slightly higher than the mean of IS-mid. Interestingly, the 95% confidence intervals of the upper and lower bounds of IS, IS-mean and PDS do not contain the true value of price discovery contribution.

## 3.4 Modified two-market "Roll" Model

In the fourth simulation example, we modify the first model in such a way so that it produces a structural price discovery contribution of 70% for Market 1 and 30% for Market 2. To do this, we define a binary variable $D$, such that $D = 1$ with probability 0.7 and $D = 0$ with probability 0.3. We assume that the efficient price is driven by *i.i.d.* non-trade information which is revealed contemporaneously only to Market 1 70% of the time and the rest of the time to Market 2. We keep the model simple by assuming no liquidity effect ($\lambda = 0$) and identical trade cost, $c$, for both markets. Efficient price is defined the same way as in first example (eq. (23)) and the transaction prices are defined as follows:

$$p_{1t} = Dm_t + (1 - D)m_{t-1} + cq_{1t} \tag{26}$$

13

$$p_{2t} = (1 - D)m_t + Dm_{t-1} + cq_{2t} \qquad (27)$$

The structural price discovery shares are 70% for Market 1 and 30% for Market 2. We proceed with the simulation exercise in the same way as before.

[**Insert Table 4 Here**]

Table 4 summarizes the simulation results. IS means of IS lower and upper bounds are 50.8% and 80.5%. In contrast, the mean of PDS is 67.5% and the 95% confidence interval of PDS contains the true share. The mean of IS-mid estimates is 65.6% but its 95% confidence interval does not contain the true share.

# 4 Empirical Application: Price Discovery in S&P 500 ETF Market

In this section, we use IS and PDS to quantify and analyze price discovery in the market for ETFs which track the S&P 500 index. We examine two competing S&P 500 ETFs, SPY and IVV, and discuss the effect of duplication of ETFs on price discovery. We first give an overview of the market for S&P 500 ETFs. We then review the existing literature on S&P 500 ETFs, describe our data and present our results and analysis.

## 4.1 An Overview of S&P 500 Exchange-Traded Funds (ETFs) Market

In the past decade, the U.S. stock market has been characterized by a new market phenomena which we call "duplication of ETFs". More precisely, this refers to the proliferation of ETFs that tracks an identical index. For example, SPY (issued by SPDR), IVV (issued by iShares) and VOO (issued by Vanguard) track the S&P 500 index; IWM (issued by iShares), VTWO (issued by Vanguard) and TWOK (issued by SPDR) track the Russel 2000 index; and QQEW (issued by First Trust) and QQQE (issued by Direxion) track the NASDAQ-100 equal-weighted index. Natural questions to ask are why this duplication is occurring and what effect does this duplication have on market prices. In our application, we address

the second question from a price discovery perspective. The duplication of ETFs shares similarity with market fragmentation as far as competition is concerned. Therefore, price discovery analysis of competing ETFs fits agreeably into this line of research.

Among the aforementioned index ETFs, we particularly focus on the S&P 500 ETFs because they are the most popular and highly traded. S&P 500 ETFs are also highly liquid assets with very low expense ratios and command a larger portion of market share among other index ETFs. There are currently three ETFs that track S&P 500 index- SPY, IVV and VOO.

[**Insert Table 5 here**]

Table 5 and 6 provide a brief comparison among SPY, IVV and VOO. SPY was introduced to the market first in 1993 and in fact, was the very first ETF of its kind. IVV was issued next in 2000 and VOO was introduced recently in 2010. Table 5 also reveals that they are similar to each other in terms of performance measures. Although VOO is the newest ETF, it is popular among traders due to its impressively low expense ratio (0.05%). However, VOO still hasn't managed to capture significant market share since SPY and IVV command almost 91.75% of the total market capitalization for S&P 500 ETFs.

[**Insert Table 6 here**]

Analysis of Table 6 shows that, in terms of top 10 holdings, SPY and IVV are more similar to each other than VOO. This is also true when we compare the sector-wise decomposition of these three ETFs. The market price data shows that the prices of SPY and IVV are very close to each other while VOO is bit different.

There are two additional features of S&P 500 ETFs that need to be discussed here in order to have a better understanding of the price dynamics of these ETFs. These are the tracking errors of ETFs and the arbitrage opportunities in ETF trading.

The S&P 500 index uses a market capitalization weighting structure to construct its portfolio. However, S&P 500 ETFs cannot exactly replicate these portfolio weights for several reasons. First, there is a copyright issue. And second, portfolio weights of the S&P 500 index are constantly changing depending on the change in market capitalization of the

underlying assets. But instant portfolio re-balancing for an ETF is costly and therefore, their portfolio weights are not identical to the S&P 500 index. This creates tracking error in the price of each S&P 500 ETF. Since a low tracking error of an ETF makes it more attractive for the ETF investors, all the ETFs issuers have strong incentives to reduce this tracking error as much as possible. Therefore, the tracking errors of each ETF are bounded.

Arbitrage opportunities can be created in ETF trading in two different ways. First, an arbitrage opportunity can be created between the ETF price and its Net Asset Value or NAV (e.g. Ben-David, Franzoni, Moussawi, 2014 ; Madhavan and Sobczyk, 2014).[9,10,11] Second, an arbitrage opportunity can be created between two similar ETFs which track the identical index (e.g. Marshall et al, 2013). The Authorized Participants(APs) can only take advantage of the first type of arbitrage opportunity.[12] For example, if during the closing hour of trading, the ETF price exceeds its NAV, the APs can buy the underlying securities of that ETF from the secondary market and submit them to the ETF issuers in exchange of new ETFs in the primary market. The APs can then sell the ETFs in the secondary market at a premium. The APs do exactly the opposite when the price of an ETF falls below its NAV. They buy ETF at discount from the secondary market, redeem the ETFs into its underlying stocks in the primary market and then sell the underlying securities at a profit in the secondary market. In contrast, an arbitrage opportunity between two similar or nearly identical ETFs can occur at any time during the trading hours. Any ETF investors (retail or institutional) can take advantage of this. Let us consider the case of SPY and IVV. If the price of SPY exceeds the price of IVV at any time during the day, there is a strong incentive for investors, who treat both of them as close substitutes, to sell SPY at the high price and buy IVV at the low price. This would allow the investors to sell the newly bought IVV at a premium when the price of IVV finally catches up with SPY.

---

[9]NAV per share is computed once a day based on the closing market prices of the underlying securities in the ETF's portfolio.

[10]Ben-David, Franzoni, Moussawi (2014) investigate the effect of ETFs on their underlying stocks and find that stocks owned by ETFs have significantly higher intra-day and daily volatility.

[11]Madhavan and Sobczyk (2014) utilize the arbitrage link between ETF closing price and its NAV and propose a state-space model of ETF price dynamics.

[12]APs are institutional investors of ETFs who usually has legal contract with the ETF issuers.

## 4.2 Price Discovery in S&P 500 ETFs (SPY and IVV): Previous Literature and Research Agenda

Marshal et al (2013) argue that even though SPY and IVV are not perfect substitutes investors consider them as close substitutes and, when the mispricing is allowed, an arbitrage opportunity is created between them. They also point out that one possible source of these ETFs being mispriced is the difference in price discovery between these two assets. More importantly, Marshal et al (2013) suggest that the prices of SPY and IVV should not diverge from each other and, whenever there is significant dispersion between the two prices, arbitrage opportunities make the two prices converge to each other. As a result, the prices are co-integrated with co-integrating vector $\theta = [1, -1]'$. This also makes them an ideal candidate to analyze their price discovery in Hasbrouck's (1995) cointegration setup as described in Section 3.

Fang and Sanger (2012) examine price discovery across SPY, IVV and the reconstructed price series for the S&P 500 index. The constructed price series of the S&P 500 index captures the second-by-second price movement in the underlying securities of the S&P 500 ETFs. They find that SPY and IVV contribute half of the price discovery share compared to their underlying stocks. They also look into price discovery across SPY and IVV and using IS they find that both of them contribute equally in price discovery. A problem with their findings is the lack of interpretation in their reported results. For example, in Table 1 of their paper, they report that during 2006 Q4, SPY contributes 51.4%, IVV contributes 52.4% and underlying component assets contribute 29.5%. The contributions add up to more than 100%. Similarly, in Table 2, when they look into SPY and IVV, they report SPY contributes 85.5% and IVV contributes 82.4% of the price discovery in the whole sample period. The reason behind this uninformative result is that they follow IS to measure price discovery.

Our analysis is motivated by the results in Marshal et al (2013) and Fang and Sanger (2012). We use PDS to give a clean decomposition of price discovery between SPY and IVV on a selected of set of trading days across a number of exchanges. Our objective is to uncover the price discovery contributions of these two ETFs in normal and unusual trading

environments. In other words, we seek to evaluate the relative importance of these two ETFs as a source of information for traders under different market conditions.

## 4.3 Interpretation of Price Discovery Measures

When traders are buying or selling either SPY or IVV, they are essentially betting on their perceived forecast regarding future market performance. Any permanent change in S&P 500 ETF prices reflect the arrival and absorption of new information regarding the future movement of the market index. Price discovery across different S&P 500 ETFs describes this process.

To interpret price discovery measure, it is important to define the set of information available to the traders of S&P 500 ETFs. According to Hasbrouck (2003), the price vector $P_t$ in the cointegrating analysis should be a comprehensive set of prices which serves as an information set that all the traders possess at time t and also "a poor proxy for common public information". The observable public information that a typical S&P 500 ETF trader has are the bid and ask price and trade price of the ETFs. We leave out the trade price from the information set in order to reduce the micro-structure noise (e.g. bid-ask bounce) in these prices. Following the previous literature, we only include the bid-ask mid-point of the two ETFs to construct the information set, so that $P_t = [P_{1t}, P_{2t}]$ where $P_{1t}$ = Bid-Ask mid-quote of SPY at time, $t$ and $P_{2t}$ = Bid-Ask mid-quote of IVV at time, $t$. We use this price vector in the VECM to get the estimated parameters to derive the price discovery measures.

Given our definition of $P_t$, it is straightforward to interpret the price discovery share of an individual ETF. Suppose, SPY is estimated to have an X% price discovery share (according to IS or PDS), it can be interpreted in following ways:

1. SPY contributes X% of the volatility of the innovation to the common random walk efficient price.

2. If $X\% > 50\%$, then SPY will be dominant in price discovery share. In other words, SPY will be the price leader. Therefore, SPY price will be the first to adjust to a new information about the fundamental value. It will be considered as the more important source of information regarding future movement in market index or the overall market

performance.

Based on the analysis in Yan and Zivot (2010), Putniņš (2013) argues that an asset price which is first to adjust (the price leader) also has the potential to be more noisy than the follower. When the transient noise levels differ significantly in the two prices, IS may end up assigning higher price discovery share to the less noisy asset price even though it may not be the price leader. As a result, IS may identify the wrong asset as the price leader. PDS also shares this property of IS. However, in our application to S&P 500 ETFs the noise levels in the prices of SPY and IVV are found to be very similar and small in magnitude so that it is unlikely that IS or PDS will misidentify the price leader due to difference in noise level.

## 4.4  Data Description and Descriptive Statistics

We use the NYSE TAQ database as our source of high-frequency quotes for SPY and IVV. We choose two snapshots of data in two distinct trading environments. For the normal trading periods, we choose intra-day quotes data from Dec 3rd to Dec 7th in 2012. For abnormal and extremely volatile trading periods, we choose the quotes data of May 6th in 2010 (the day of "Flash Crash") and Aug 8th, 2011 (the day of the worst stock market fall in US since 2008)

For Dec 3rd - Dec 5th, 2012 we collect quotes data from the following stock exchanges-BATS, Nasdaq, Arca, CBOE, NSX, Boston, Philadelphia and EDGE A. For May 6th, 2010 and Aug 8th, 2011 we collect data from BATS, Nasdaq and Arca. The reason for excluding the rest of the stock exchanges for these periods is either SPY or IVV were not traded in these stock exchanges or the frequency of trade was too low. In order to be consistent with the first abnormal period, we also look into quotes only from these three stock exchanges for 8th August, 2011.

[Insert Table 7 here]

Table 7 reports the S&P volatility index, VIX, sometimes called the "fear index" for the sample considered. The average of the closing price of the VIX during the normal trading period is 16.53. In contrast, the closing price of the VIX on May 6th, 2010 was twice (closing

VIX = 32.8) as large and on Aug 8th, 2011 it was three times as large (closing VIX = 48) as they were during the normal period.

On May 6th, 2010 the US stock market experienced an abrupt crash. The abnormal plunge in the market index was first seen at 2:42 pm and the fall in prices continued for the next 20 minutes. The Dow Jones Industrial Average experienced the biggest one-day point decline during that day.

August 11th, 2011 is considered to be the worst day in Wall Street since the crisis of 2008. All three major stock market indexes (S&P 500, Dow Jones Industrial Average, NASDAQ composite) fell sharply (between 5% to 7%) during that day. The day was also known for the wide-spread panic among the investors regarding the US losing its AAA credit rating on Aug 6th, 2011.

Tick-by-tick raw trade and quote data typically contain numerous types of data errors and need to be thoroughly "cleaned" prior to being analyzed. We use the data cleaning procedure recommended for the TAQ data described by Barndorff-Nielsen et al (2008). [13] The data-cleaning steps for the bid-ask quotes involved the following- 1. Restrict data to exchange hours (9:30 am to 4:30 pm) 2. Delete entries with zero quotes. 3. Delete entries with negative spreads 4. Delete entries if spread > maximum*median daily spread 5. Delete entries for which the mid-quote is outlying with respect to surrounding entries. 6. Restrict data to a specific exchange for analysis.[14] 7. For each stock exchange dataset, we delete entries with same time stamp and use median quotes. 8. In each stock exchange dataset, when there is a time-stamp with no ask/bid price reported for it, we use the last observed ask/bid price to replace the missing values. After cleaning, for each ETF we have 25201 observations for a given stock exchange and for a given day.

[**Insert Table 8 here**]

Table 8 contains descriptive statistics for the intraday quotes of SPY and IVV in the eight different stock exchanges during a normal trading week in December, 2012. We first calculate the average 1-second continuously compounded returns for each day in that week and then

---

[13]This data cleaning routine is implemented in the R package called "highfrequency".

[14]After this step, we get intra-day time series dataset of SPY quotes and IVV quotes for each stock exchange separately.

report the average of these calculated returns. We do the same for 1-second return volatility, bid-ask spreads and number of shares traded. Table 8 reveals that in terms of average return and volatility, in every stock exchange except NSX, both ETFs' performances are very similar. IVV return is found to be abnormally volatile compared to SPY in the NSX stock exchange and this irregularity is also captured in the difference of their average returns. NASDAQ, BATS and Arca are the exchanges with highest number of trades per day and also have the lowest average bid-ask spread. CBOE, which has the lowest trades per day, also has the highest average bid-ask spread. SPY is much more heavily traded than IVV in each stock exchange.

[**Insert Table 9 here**]

Table 9 reports descriptive statistics of the day of "Flash Crash" in 2010. Compared to our sample of a normal trading week, the average 1-second return volatility on May 6th, 2010 was more than 1,000 times higher. The average 1-second returns are also 10 times lower than our previous sample. NASDAQ, BATS and Arca are again the stock exchanges with the highest number of shares traded and lowest average bid-ask spread. In all of these three exchanges the return volatility for IVV is much higher than that of SPY.

[**Insert Table 10 here**]

Table 10 reports the descriptive statistics of the day of stock market fall in August 8th, 2011. The loss in 1-second return is on average 100 times larger than that of regular trading period. The 1-second return volatility is also higher for both SPY and IVV in the three stock exchanges. One interesting point here is that the bid-ask spread of both ETFs were lower compared to May 6th, 2010. This indicates that the market turmoil on August 8th did not have a significant impact on the liquidity of SPY or IVV.

[**Insert Figure 1 through 6 here**]

Figure 1 through 6 shows the intra-day prices of SPY and IVV during the analysis periods. From these diagrams, it is clear that the two ETF prices move in tandem throughout the day (i.e. highly cointegrated) . The only exception was the short period in the afternoon

during the "Flash Crash" when the SPY price plummeted by a significant amount compared to IVV.

## 4.5   Estimation and Results

We estimate and report PDS for each exchange in Table 11 during the two selected periods. For the normal trading period (Dec 3rd – Dec 7th, 2012), we first estimate PDS of SPY and IVV in every day for a given stock exchanges and then report the daily average of PDS. We also do the same for abnormal periods- May 6th, 2010 and Aug 8th, 2011.

[Insert Table 11 here]

The third column of Table 11 reports PDS for the normal trading week in December, 2012 in eight stock exchanges. SPY leads IVV in price discovery in every stock exchange considered. On average, SPY contributes 61.25% of the price discovery compared to IVV across all stock exchanges. Interestingly, for the NASDAQ and Philadelphia exchanges, IVV price is found to be an almost equally important source of trade-related information as it contributes 47% of the price discovery. Although, the daily average PDS indicates that SPY is leading IVV everywhere, there are days for which IVV leads SPY in some particular exchanges. Among the 40 cases (eight stock exchanges in five days), IVV contributes more to price discovery than SPY in 9 occasions. The fourth column reports PDS across SPY and IVV on the day of Flash Crash in NASDAQ, BATS and Arca. We find that SPY leads IVV in every stock exchange by a large margin. On an average, in every stock exchange SPY contributed 95% of the price discovery. The fifth column reports the result during August 11, 2011. Here, we again find that in each market SPY contributes much more to price discovery share than IVV. On an average, the contribution to price discovery of SPY in each stock exchange was about 75%.

We interpret these results in the following way. Our goal is to check whether duplication in the S&P 500 ETFs provides traders with a better source of trade related information. Looking at three snapshots in two different environments, we find a consistent result. Although there is more than one ETF tracking the S&P 500 index, traders consider SPY to be a better source of information. This reliance becomes extreme or significantly high in

the event of abnormal jumps or falls in intra-day prices (Flash Crash, 2010 or August stock market fall in 2011). Particularly, on the day of Flash Crash, IVV price is found to be very less informative as far as "capturing the new information in a timely manner" is concerned.

A hypothesis that we think is feasible to explain this outcome is the attributes based on the buyers of ETFs. The answer to the question that "Who buys S&P 500 ETFs and Why?" can give us a much better idea to explain the dominance of one particular S&P 500 ETF (namely SPY) in price discovery. If more informed traders choose to trade in one particular S&P 500 ETF most of the time, then by definition that ETF should contribute more to price discovery. Therefore, we think that the distribution of institutional and retail buyers of S&P 50 ETF and their objectives (eg. hedging against market makers) behind investing in these ETFs can help us understand the dominance of SPY over IVV. In previous literature, liquidity of assets has also been found to be an important factor in explaining the price discovery contribution. However, in this case, we have observed that both ETFs are highly liquid and their liquidity measures like the bid-ask spreads are very close to each other in both normal and volatile conditions. Trading volume is also a key factor behind the dominance of SPY. Analyzing the descriptive statistics tables (Table 8, 9 and 10), we find that IVV is comparatively highly traded in three stock exchanges- NASDAQ, BATS and Arca. However, even in these stock exchanges, during the normal period, the number of shares traded of IVV is only about 5% of that of SPY. During the volatile period, this ratio becomes less than 1%. This complete dominance of SPY over IVV in terms of trading volume can also explain the higher price discovery contribution of SPY.

# 5 Empirical Application: Comparative Assessment between PDS and IS

In this section we provide a comparative assessment between PDS and IS. First, we show their difference in a setting which is similar to first empirical application. That is, measuring price discovery across SPY and IVV in different stock exchange. But here, we only consider one day from the normal trading period to show our result. Next, we demonstrate a more

conventional application of price discovery which is analyzing price discovery of a cross listed asset. We pick SPY as the cross listed asset and measure price discovery between NASDAQ and BATS where it is most heavily traded. We report our result using different time intervals and compare the estimates of PDS and upper bound, lower bound and mean of IS.

## 5.1 Comparative Assessment between PDS and IS for S&P 500 ETFs

Here we utilize a subset of our previous results to compare IS and PDS. A known drawback of IS, as we have discussed earlier is that it can report the contribution of a given asset price to the price discovery in a range and this range can be so wide that it becomes difficult to have a meaningful interpretation of these results. Hasbrouck (1995) recognized this potential problem of IS and proposed the use of high-frequency data (e.g. quotes at every second) to get a tighter bound for IS. Here we look into the price discovery contributions between SPY and IVV only on December 3rd, 2012 which was a normal trading day and we conduct our analysis in eight different stock exchanges. We find that even with high frequency 1-sec interval quotes data, IS produces a very large range.

We look into the bid-ask mid-quotes of these as before and estimating the VECM equation to derive the parameters necessary for the calculation of IS and PDS. We use equation (11) to calculate IS and equation (15) to calculate PDS. For the IS calculation, it is important to note which of the two prices was placed first in the price vector. We first put log of bid-ask mid-quotes of SPY as the first element in the price vector and calculate the upper (lower) bound IS for SPY (IVV). We then place log of bid-ask mid-quotes of IVV as the first element and calculate the IS again. This gives us the lower (upper) bound IS for SPY (IVV). We also take the average of these two bounds and report it. We call it "IS-mean" which is a method proposed by Baillie et al (2002) for a unique measure of IS.

[Insert Table 12 here]

The 3rd and 4th column of Table (12) reports the upper and lower bound of IS. If the difference between upper and lower bound gets larger, we face the identification problem

24

in determining the price leader out of the two. A closer look at these two columns tells us that in the case NASDAQ, Arca, Boston, Philadelphia and EDGE A, the upper bounds of IS for each ETF identify themselves as price "leaders" and the lower bounds of the same ETF identify themselves as "followers". On the other hand, our measure, PDS gives a clean decomposition, reports a unique value for each ETF and more importantly, identifies the price "leader" correctly in every occasion. The IS-mean also identifies the same leaders as PDS but the contribution reported by IS-mean is found to be under-estimated in every case. Particularly, in the case of BATS and CBOE, IS-mean under-estimates the price discovery contributions by more than 10%. We also estimate the standard error for both measures (IS and PDS) in every case by bootstrap method .[15] For both measures, the reported boot-strap standard errors are very low and we also do not find a significant difference between IS and PDS in terms of standard errors reported.

## 5.2    Comparative Assessment between PDS and IS: Quotes at higher time interval

Another limitation of IS is that the gap between upper and lower bounds gets significantly large if data at higher interval are used for analysis. Studies have shown that quotes data with more than 1-second interval have substantial contemporaneous residual correlation that results in wide range of upper and lower bounds for the IS (see Gramming et al., 2005; Theissen, 2002 and Huang 2002).

[Insert Table 13 here]

Table 13 reports the results of an application where we focus on a single cross-listed ETF (SPY) and the price discovery contribution between two competing stock exchanges (NASDAQ and BATS). We start our analysis with the tick-by-tick data (1 second interval) and then continue to calculate IS and PDS at lower frequency observations (data with 5

---

[15]Bootstrap method is done following Grammig et al (2005). First, VECM parameters are estimated and we derive the estimated residuals from the difference of actual data and fitted data. Estimated residuals are used to simulate price series using original price series as starting values. The price discovery measure is calculated from the simulated data and the whole process is repeated 1000 times to get the mean and standard error of IS and PDS.

seconds-, 10 seconds-, 20 seconds-, 30 seconds, 40 seconds- , 50 seconds- , 1 minute- , 1 minute 30 seconds, 2 minutes- intervals). We show that as we move from high to lower frequency data, the gap between upper bound and lower bound of IS becomes very large. We also report the IS-mid and find that for all the time intervals, IS-mid identifies both stock exchanges contributing almost equally to the price discovery. In contrast, according to PDS, NASDAQ is the price "leader" in every sample with different time intervals. This result proves that PDS, unlike IS, is robust to the choice of time intervals and more importantly, it always gives a consistent and conclusive results when IS and IS-mid fail to do so.

# 6 Conclusion

In this paper we propose a new measure for quantifying a market's contribution to price discovery that is closely related to IS but is unique and order invariant. Our measure is equal to IS when VECM innovations are uncorrelated, and is similar to the mid-point IS measure as proposed by Baillie et al (2002) and is applicable in the case of $n > 2$ markets. PDS has all the benefits of IS with the added benefit of being order invariant.Our expectation is that, our new order invariant measure of price discovery, PDS will be adopted widely in the future discourse on price discovery.

Our empirical application investigates the price discovery between SPY and IVV, two ETFs that track the S&P 500 index. SPY is found to be the information leader in normal and extremely volatile market conditions.

Our results provide a useful information for ETF investors. As there are numerous ETFs that track the S&P 500 index, investors often face the dilemma in choosing an ETF for their investment portfolio. Low tracking error, low expense ratio and low tax burdens are the common determinants behind this decision. An ETF's price discovery contribution is also an important consideration for the cases where a clear pattern of price leadership is identified between two competing ETFs in a particular stock exchange, it may be possible for arbitragers to make profits by adopting pair-trading. In both cases, our new measure, PDS can provide the investors with useful information regarding ETFs.

We hope that our study on the S&P 500 ETFs will attract more attention in future to

this class of assets and their price dynamics.

Table 1: Two Markets "Roll" Model

Efficient price: $m_t = m_{t-1} + u_t, \qquad u_t \sim N(0, \sigma^2)$
Trade direction: $q_{it} = \pm 1$, each with pr. $\frac{1}{2}$ for i=1,2,
Transaction price: $p_{it} = m_t + cq_{it}$ for =1,2
where $c = 1$ and $\sigma_u = 1$ so that both market's share of price discovery is 50%.
Model 1 is simulated for 1,000 samples of 100,000 observations.
IS and PDS are computed from the estimated VECM (eq. 8) with 20 lags.

| Model 1 : structural price | Hasbrouck (1995) model: IS for Market 1 | | | |
| discovery share of market 1 = 0.5 | Upper Bound | Lower Bound | IS-Mean | PDS |
| mean | 0.78 | 0.21 | 0.500 | 0.5011 |
| Standard Deviation | 0.011 | 0.011 | 0.011 | 0.017 |
| 95% confidence interval | [0.766, 0.812] | [0.188, 0.235] | [0.478,0.522] | [0.4662, 0.5359] |

Table 2: Two Markets with Private Information

---

Efficient price: $m_t = m_{t-1} + \lambda q_{1t}$
Trade direction: $q_{it} = \pm 1$, each with pr. $\frac{1}{2}$ for i=1,2,
Transaction price: $p_{1t} = m_t + c_1 q_{1t}$ and $p_{2t} = m_{t-1} + c_2 q_{2t}$
where $c_1 = 1, c_2 = 1, \lambda = 1$ so that market 1's share of price discovery is 100%.
Model 2 is simulated using parameter values for 1,000 samples of 100,000 observations.
IS and PDS are computed from the estimated VECM (eq. 8) with 20 lags.

| Model 2 : structural price discovery share of market 1 = 1.0 | Hasbrouck (1995) model: IS for Market 1 | | | |
| | Upper Bound | Lower Bound | IS-mean | PDS |
|---|---|---|---|---|
| mean | 0.999 | 0.999 | 0.999 | 0.999 |
| Standard Deviation | 0.0002 | 0.0002 | 0.0002 | 0.0002 |
| 95% confidence interval | [0.999, 1.0] | [0.99, 1.0] | [0.99, 1.0] | [0.999, 1.0] |

Table 3: Two Markets with Public and Private Information

Efficient price: $m_t = m_{t-1} + \lambda q_{1t} + u_t$ where $u_t \sim N(0, \sigma_u^2)$
Trade direction: $q_{it} = \pm 1$, each with pr. $\frac{1}{2}$ for i=1,2,
Transaction price: $p_{1t} = m_t + c_1 q_{1t}$ and $p_{2t} = m_{t-1} + c_2 q_{2t}$
where $c_1 = 1, c_2 = 0, \lambda = 1, \sigma_u = 1$ so that the share of price discovery in market 1 is 100%.
Model 3 is simulated for 1000 samples of 100,000 observations.
IS and PDS are computed from the estimated VECM (eq. 8) with 20 lags.

| Model 3 : structural price | Hasbrouck (1995) model: IS for Market 1 | | | |
|---|---|---|---|---|
| discovery share of market 1 = 1.0 | Upper Bound | Lower Bound | IS-mean | PDS |
| mean | 0.984 | 0.900 | 0.942 | 0.960 |
| Standard Deviation | 0.003 | 0.008 | 0.005 | 0.006 |
| 95% confidence interval | [0.978, 0.990] | [0.884, 0.916] | [0.932, 0.952] | [0.948, 0.972] |
